# Buffer kinetics shape the spatiotemporal patterns of IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals

Sheila L. Dargan and Ian Parker

Department of Neurobiology and Behavior, University of California Irvine, CA 92697-4550, USA

Ca<sup>2+</sup> liberation through inositol 1,4,5-trisphosphate receptors (IP<sub>3</sub>Rs) plays a universal role in cell regulation, and specificity of cell signalling is achieved through the spatiotemporal patterning of Ca<sup>2+</sup> signals. IP<sub>3</sub>Rs display Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release (CICR), but are grouped in clusters so that regenerative Ca<sup>2+</sup> signals may remain localized to individual clusters, or propagate globally between clusters by successive cycles of Ca<sup>2+</sup> diffusion and CICR. We used confocal microscopy and photoreleased IP<sub>3</sub> in *Xenopus* oocytes to study how these properties are modulated by mobile cytosolic Ca<sup>2+</sup> buffers. EGTA (a buffer with slow 'on-rate') speeded Ca<sup>2+</sup> signals and 'balkanized' Ca<sup>2+</sup> waves by dissociating them into local signals. In contrast, BAPTA (a fast buffer with similar affinity) slowed Ca<sup>2+</sup> responses and promoted 'globalization' of spatially uniform Ca<sup>2+</sup> signals. These actions are likely to arise through differential effects on Ca<sup>2+</sup> feedback within and between IP<sub>3</sub>R clusters, because Ca<sup>2+</sup> signals evoked by influx through voltage-gated channels were little affected. We propose that cell-specific expression of Ca<sup>2+</sup>-binding proteins with distinct kinetics may shape the time course and spatial distribution of IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals for specific physiological roles.

Cytosolic Ca<sup>2+</sup> ions regulate numerous aspects of cellular activity in virtually all cell types (Berridge *et al.* 2000). This versatility is made possible by the diverse mechanisms by which Ca<sup>2+</sup> signals are generated and transmitted to act over very different time and distance scales (Berridge *et al.* 2000; Marchant & Parker, 2000). Endogenous Ca<sup>2+</sup> binding proteins play a key role in determining the magnitude, kinetics and spatial distribution of cytosolic Ca<sup>2+</sup> signals, and typically buffer most (> 90 %) of the total Ca<sup>2+</sup> ions in the cytosol (Berridge *et al.* 2000). As well as simply reducing the availability of free cytosolic Ca<sup>2+</sup> ions, buffers also affect their diffusional mobility. Immobile buffers reduce the effective diffusion coefficient for Ca<sup>2+</sup>, whereas mobile buffers can act as a 'shuttle' to speed Ca<sup>2+</sup> diffusion in the presence of immobile buffers (Stern, 1992; Roberts, 1994). It is thus likely that cells utilize buffers to shape Ca<sup>2+</sup> signals for their specific functions; a notion supported by observations that different cell types – particularly subpopulations of neurons – selectively express mobile Ca<sup>2+</sup> binding proteins (e.g. parvalbumin and calretinin) with differing properties (Andressen *et al.* 1993). However, the functional consequences of selective buffer expression remain unclear (Neher, 2000; Schwaller *et al.* 2002).

Most experimental and theoretical investigations of cellular Ca<sup>2+</sup> buffers have concentrated on signals arising from a fixed 'pulse' of Ca<sup>2+</sup>, e.g. Ca<sup>2+</sup> entry through voltage- or ligand-gated membrane channels (e.g. Lee *et al.*

2000a,b). A more complex case involves Ca<sup>2+</sup> liberation from intracellular stores through IP<sub>3</sub>Rs. The opening of these channels shows dual positive and negative regulation by cytosolic Ca<sup>2+</sup> (Iino, 1990; Finch *et al.* 1991; Bezprozvanny *et al.* 1991; Mak *et al.* 1998), leading to a mechanism of CICR whereby small elevations of cytosolic [Ca<sup>2+</sup>] promote channel opening to liberate further Ca<sup>2+</sup>. Buffers are thus expected to exert a powerful effect on signals arising through intracellular Ca<sup>2+</sup> liberation, as they will affect not only the fate of Ca<sup>2+</sup> ions already deposited into the cytosol, but also influence the subsequent liberation of Ca<sup>2+</sup> by modulating feedback onto IP<sub>3</sub>Rs.

IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals display complex spatial and temporal patterning. Stimulation by relatively high [IP<sub>3</sub>] typically gives rise to repetitive, propagating Ca<sup>2+</sup> waves (Lechleiter & Clapham, 1992). Lower [IP<sub>3</sub>] evokes transient, localized Ca<sup>2+</sup> elevations, christened 'Ca<sup>2+</sup> puffs', which have been visualized in oocytes and other cell types (Yao *et al.* 1995; Bootman *et al.* 1997). Puffs are believed to arise because localized CICR causes the concerted opening of channels within localized clusters of a few tens of IP<sub>3</sub>Rs, which act as functionally discrete Ca<sup>2+</sup> release units (Callamaras *et al.* 1998a,b; Swillens *et al.* 1999). Puffs may serve both as local Ca<sup>2+</sup> signals in their own right, and as 'building blocks' from which Ca<sup>2+</sup> waves are generated. When [IP<sub>3</sub>] is sufficiently high, Ca<sup>2+</sup> diffusing from one release site triggers CICR at neighbouring sites a few

**Table 1. Summary of kinetic parameters and diffusion distances for binding and unbinding of Ca<sup>2+</sup> to EGTA and BAPTA**

	EGTA	BAPTA
Apparent $K_d$ (nM) (at pH 7.2)	150	160
$K_{on}$ ( $\mu\text{M}^{-1} \text{s}^{-1}$ )	3–10	100–1000
$K_{off}$ ( $\text{s}^{-1}$ )	0.5–1.5	16–160
$\tau_{\text{dwell}}$ (ms)	700–2000	6–60
$d_{\text{shuttle}}$ ( $\mu\text{m}$ )	28–50	3–9
$\tau_{\text{capture}}$ (ms) (for $B = 270 \mu\text{M}$ )	4–10	0.04–0.4
$d_{\text{capture}}$ ( $\mu\text{m}$ ) (for $B = 270 \mu\text{M}$ )	0.7–1	0.07–0.2

Apparent affinities (Morris *et al.* 1999) and lower and upper estimates for on-rates ( $K_{on}$ ) (Naraghi, 1997; Nagerl *et al.* 2000), were used to derive off-rates ( $K_{off} = K_d K_{on}$ ) for EGTA and BAPTA. Dwell time ( $\tau_{\text{dwell}}$ ) reflects how long Ca<sup>2+</sup> will remain bound to each buffer, where  $\tau_{\text{dwell}} = 1/K_{off}$ . The corresponding mean distances over which the Ca<sup>2+</sup>–buffer complex will diffuse before releasing bound Ca<sup>2+</sup> ( $d_{\text{shuttle}}$ ) were estimated as  $\sqrt{(6D_{\text{Cabuffer}}\tau_{\text{dwell}})}$ , assuming a diffusion coefficient ( $D_{\text{Cabuffer}}$ ) of  $200 \mu\text{m}^2 \text{s}^{-1}$ . Mean capture times before a Ca<sup>2+</sup> ion binds to EGTA or BAPTA were calculated as  $\tau_{\text{capture}} = 1/(K_{on}B)$  (Stern, 1992; Roberts, 1994), where  $B$  is the concentration of Ca<sup>2+</sup>-free binding sites on the buffer, assuming that Ca<sup>2+</sup> ions in the cytosol are bound to immobile endogenous buffers for 90 % of the time. The corresponding mean distances that a Ca<sup>2+</sup> ion would diffuse before capture ( $d_{\text{capture}}$ ) were calculated as  $d_{\text{capture}} = \sqrt{(D_{\text{Ca}}\tau_{\text{capture}})}$ , assuming an apparent diffusion coefficient ( $D_{\text{Ca}}$ ) of  $20 \mu\text{m}^2 \text{s}^{-1}$  for Ca<sup>2+</sup> in the presence of immobile endogenous buffers.

microns away, giving rise to saltatory waves propagating from site to site (Yao *et al.* 1995; Bootman *et al.* 1997; Berridge, 1997; Callamaras *et al.* 1998a,b). Thus, Ca<sup>2+</sup> diffusion and feedback onto the IP<sub>3</sub>R act over two very different distance scales: rapid (microsecond) interactions over nanometre scales between individual IP<sub>3</sub>Rs within a cluster to generate local Ca<sup>2+</sup> puffs, and slower (tens of milliseconds) interactions over micrometre scales between release sites to generate global Ca<sup>2+</sup> waves.

In this paper, we studied how Ca<sup>2+</sup> buffers with differing kinetics modulate Ca<sup>2+</sup> interactions over these widely divergent distance and time scales. Our objectives were to: (1) explore how cells might employ buffers to shape Ca<sup>2+</sup> signals for their specific purposes, and (2) use buffers as a tool to derive mechanistic information about Ca<sup>2+</sup> interactions at scales otherwise inaccessible to direct visualization.

We utilized *Xenopus* oocytes as a model cell system to image the perturbations of Ca<sup>2+</sup> signalling resulting from intracellular injections of two mobile buffers, EGTA and BAPTA. The oocyte has advantages that intracellular Ca<sup>2+</sup> liberation is mediated solely through type 1 IP<sub>3</sub>Rs (Parys *et al.* 1992); its large size greatly facilitates intracellular injections; and it is among the best characterized cells for Ca<sup>2+</sup> signalling. EGTA and BAPTA were selected for study because these well-characterized exogenous buffers

display similar affinities yet have very different Ca<sup>2+</sup> binding kinetics (Tsien, 1980). EGTA has an on-rate ( $\sim 3\text{--}10 \mu\text{M}^{-1} \text{s}^{-1}$ ; Table 1) sufficiently fast to bind Ca<sup>2+</sup> ions diffusing over the micrometre distances between Ca<sup>2+</sup> release sites (Roberts *et al.* 1994; Horne & Meyer, 1997; Song *et al.* 1998; Kidd *et al.* 1999), but too slow to influence short range feedback of Ca<sup>2+</sup> between individual IP<sub>3</sub>Rs at individual puff sites. On the other hand, BAPTA has a much faster on-rate ( $100\text{--}1000 \mu\text{M}^{-1} \text{s}^{-1}$ ; Table 1) and, whereas it is expected to disrupt local Ca<sup>2+</sup> feedback within IP<sub>3</sub>R clusters, it may actually enhance coupling between release sites by acting as a ‘shuttle buffer’ (Stern, 1992; Roberts, 1994). We show here that injection of the slow buffer EGTA into the oocyte promotes a ‘balkanization’ of Ca<sup>2+</sup> liberation as transient, autonomous local release events, whereas the fast buffer BAPTA results in a ‘globalization’ of spatially diffuse Ca<sup>2+</sup> signals. Moreover, these spatial changes are accompanied by profound changes in kinetics of Ca<sup>2+</sup> signals, suggesting that Ca<sup>2+</sup> interactions between release sites play a large part in setting the duration of Ca<sup>2+</sup> spikes.

## METHODS

### Preparation of *Xenopus* oocytes

*Xenopus laevis* were anaesthetized by immersion in 0.17 % MS-222 for 15 min and killed by decapitation in adherence with protocols approved by the UC Irvine Institutional Animal Care and Use Committee. Oocytes (stage V–VI) were manually plucked and collagenase-treated ( $0.5 \text{ mg ml}^{-1}$  for 30 min) before storage in Barth’s solution (composition (mM): NaCl, 88; KCl, 1; NaHCO<sub>3</sub>, 2.4; MgSO<sub>4</sub>, 0.82; Ca(NO<sub>3</sub>)<sub>2</sub>, 0.33; CaCl<sub>2</sub>, 0.41; Hepes, 5; pH 7.4) containing  $0.1 \text{ mg ml}^{-1}$  gentamicin at 17°C for 1–7 days before use.

### Microinjection of oocytes

Intracellular microinjections were performed using a Drummond microinjector. Oocytes were first loaded with Oregon Green 488 BAPTA 1 (OG-1) together with caged IP<sub>3</sub> (D-*myo*-inositol 1,4,5-trisphosphate, P<sub>4(5)</sub>-(1-(2-nitrophenyl)ethyl) ester) to respective final intracellular concentrations of 48 and  $8 \mu\text{M}$ ; assuming  $1 \mu\text{l}$  cytosolic volume. After allowing 30 min for intracellular distribution, control Ca<sup>2+</sup> responses were imaged. A specified volume of buffer solution was then injected through a fresh micropipette and the pipette was immediately removed to minimize leakage. Ca<sup>2+</sup> responses were then imaged after allowing  $\sim 20$  min for intracellular equilibration of buffer concentration, and sequential injections and recordings were made in this way to examine the effects of stepwise increases in buffer concentration. Injection solutions contained 5 mM of either EGTA or BAPTA together with 2.5 mM CaCl<sub>2</sub> (pH 7.25, with KOH), such that the buffers were half-saturated with Ca<sup>2+</sup>. To obtain high final intracellular concentrations ( $> 270 \mu\text{M}$ ), stock buffer concentrations were increased to 10 mM (including 5 mM CaCl<sub>2</sub>) and buffer was administered by a series of repeated 10 nl injections. Control experiments, where high cytosolic buffer concentrations were attained following single injections of EGTA or BAPTA, gave similar results to those where the concentration was raised in a stepwise manner. Moreover, responses evoked in control oocytes (not injected with buffer) remained consistent over periods up to 3 h.

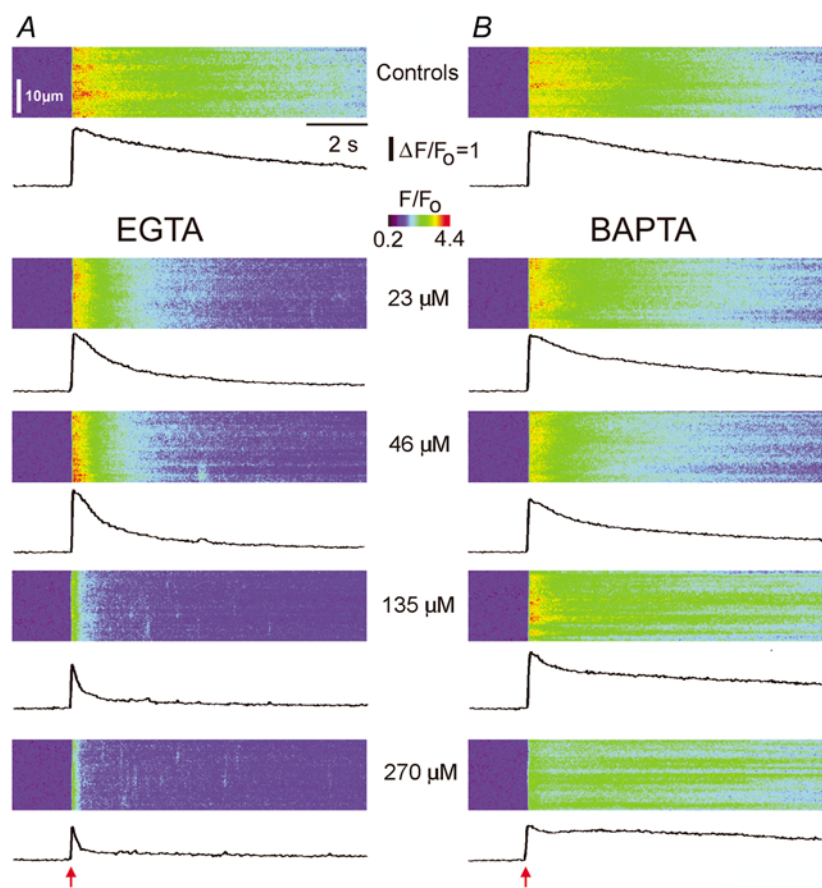

### Confocal laser scanning microscopy

Confocal Ca<sup>2+</sup> images were obtained using a custom-built line-scan confocal scanner interfaced to an Olympus IX70 inverted microscope (Parker *et al.* 1997). Recordings were made at room temperature, imaging in the animal hemisphere of oocytes bathed in normal Ringer solution (composition (mM): NaCl<sub>2</sub>, 120; KCl, 2; CaCl<sub>2</sub>, 1.8; Hepes, 5; pH 7.3). The laser spot of a 488 nm argon ion laser was focused with a ×40 oil immersion objective (NA 1.35) and scanned every 16 ms along a 50 μm line, of which representative trimmed sections are shown in the figures. Emitted fluorescence was detected at wavelengths > 510 nm through a confocal pinhole providing lateral and axial resolutions of about 0.3 and 0.5 μm, respectively. The scan line was focused at the level of the pigment granules and images were collected through a coverglass forming the base of the recording chamber. Fluorescence signals are expressed as ratios ( $F/F_0$  or  $\Delta F/F_0$ ) of the fluorescence ( $F$ ) at each pixel relative to the mean resting fluorescence ( $F_0$ ) at that pixel prior to stimulation. IP<sub>3</sub> was photo-released from a caged precursor by delivering flashes of UV light, focused uniformly throughout a 200 μm spot surrounding the image scan line (Callamaras & Parker, 1998). The amount of

photo-released IP<sub>3</sub> was controlled (in a linear manner) by varying flash duration. Each flash consumes only a negligible fraction of the caged IP<sub>3</sub> (Callamaras & Parker, 1998), thus it was possible to acquire numerous consistent responses using repeated flashes. Intervals of > 60 s were allowed between recordings to allow IP<sub>3</sub>Rs to recover from desensitization and for cytosolic [Ca<sup>2+</sup>] to recover to basal levels. Images were constructed and processed using custom routines written in the IDL programming environment (Research Systems, Boulder, CO, USA), and measurements were exported to Microcal Origin 6.0 (OriginLab, Northampton, MA, USA) for analysis and graphing.

### Expression of N-type Ca<sup>2+</sup> channels

Plasmids containing cDNA clones coding for the N-type Ca<sup>2+</sup> channel  $\alpha_{1B-d}$  and  $\beta_3$  subunits (Lin *et al.* 1997) were linearized and transcribed *in vitro*. Equal quantities of each subunit cRNA were mixed to a final concentration of 0.1–1 μg μl<sup>-1</sup> and injected (50 nl) into defolliculated oocytes 3–5 days prior to imaging and electrophysiological recording. Membrane potential was held at -60 mV using a two-electrode voltage clamp (Gene Clamp 500, Axon Instruments, Foster City, CA, USA), and stepped to +30 mV

**Figure 1. Modulation of IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals by EGTA and BAPTA**

Confocal line-scan images illustrate Ca<sup>2+</sup> signals evoked by photoreleased IP<sub>3</sub> in the presence of increasing concentrations of buffer. In each image, distance is depicted vertically, time runs from left to right and increasing Oregon Green 488 BAPTA 1 (OG-1) fluorescence ratio ( $\Delta F/F_0$ ; proportional to [Ca<sup>2+</sup>]<sub>free</sub>) is represented by 'warmer' colours as denoted by the colour bar. Identical photolysis flashes (normalized intensities of 1.5 in A and 1.9 in B) were delivered at the arrows. Traces below each image show fluorescence profiles averaged over 100 pixel (6.6 μm) regions. A, upper panel shows response before loading buffer, and subsequent panels illustrate responses after sequentially loading the same oocyte with EGTA to the final intracellular concentrations stated. B, similar records from a different oocyte showing the effects of increasing concentrations of BAPTA.

to induce opening of N-type  $\text{Ca}^{2+}$  channels expressed in the plasma membrane.  $\text{Ca}^{2+}$  imaging was as described above, except that  $[\text{Ca}^{2+}]$  in the Ringer solution was 6 mM.

### Reagents

OG-1, caged  $\text{IP}_3$  and BAPTA were from Molecular Probes Inc. (Eugene, OR, USA); all other reagents were from Sigma Chemical Co. (St Louis, MO, USA).

## RESULTS

### Actions of buffers on $\text{IP}_3$ -evoked $\text{Ca}^{2+}$ signals

We compared the actions of fast (BAPTA) and slow (EGTA)  $\text{Ca}^{2+}$  buffers on  $\text{IP}_3$ -evoked intracellular  $\text{Ca}^{2+}$  signals. *Xenopus* oocytes were loaded with the indicator OG-1 together with caged  $\text{IP}_3$ , and confocal line-scan

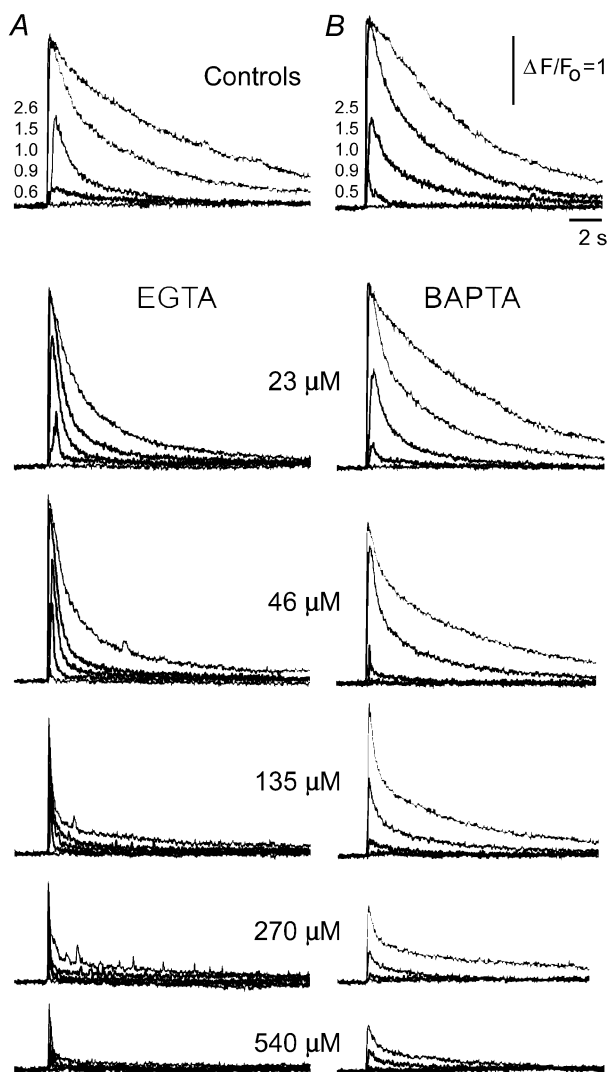

images of  $\text{Ca}^{2+}$ -dependent fluorescence were acquired along a 50  $\mu\text{m}$  scan line focused  $\sim 5 \mu\text{m}$  inward from the cell surface where  $\text{Ca}^{2+}$  release sites are concentrated (Callamaras & Parker, 1999).  $\text{IP}_3$  was photo-released by UV light flashes, with durations set by an electronic shutter to provide a linear control of the relative amount of  $\text{IP}_3$  liberation. To control for variation between oocytes, flash strengths were normalized relative to that evoking a half-maximal response under control conditions (i.e. before adding buffer) in each cell.

Figure 1 illustrates  $\text{Ca}^{2+}$  images obtained at various buffer concentrations in response to a fixed flash strength, and Fig. 2 shows superimposed fluorescence traces in response to various flash strengths at each buffer concentration. Following acquisition of control records (upper panels in Figs 1 and 2), a volume of buffer solution (EGTA, Figs 1A and 2A; or BAPTA, Figs 1B and 2B) was injected into each oocyte to give a final intracellular concentration of 23  $\mu\text{M}$  (see Methods for details). Microinjection pipettes were removed immediately following injection to prevent leakage, and oocytes were left for  $\sim 20$  min to ensure uniform buffer distribution and re-equilibration of  $\text{Ca}^{2+}$  ions in the cytosol before imaging responses to the same series of UV flashes. This procedure was then repeated, sequentially injecting increasing volumes of buffer solutions to image  $\text{Ca}^{2+}$  signals at progressively higher buffer concentrations (46–540  $\mu\text{M}$ ).

The data in Figs. 1 and 2 are representative of observations in 45 oocytes (EGTA,  $n = 21$ ; BAPTA,  $n = 24$ ). The results are analysed in the following sections, but the most striking finding was that EGTA (a  $\text{Ca}^{2+}$  buffer with slow  $\text{Ca}^{2+}$  binding kinetics) greatly abbreviated  $\text{IP}_3$ -evoked  $\text{Ca}^{2+}$  signals, whereas BAPTA (a faster  $\text{Ca}^{2+}$  buffer) slowed their decay.

### Changes in $\text{Ca}^{2+}$ signals result from increased buffering, not changes in resting $[\text{Ca}^{2+}]$ or store content

The effects described in Figs 1 and 2 might, in principle, arise either through buffering of  $\text{Ca}^{2+}$  liberated in response to  $\text{IP}_3$ , or because the added buffers chelated oocyte  $\text{Ca}^{2+}$  to cause long-term changes in basal cytosolic free  $[\text{Ca}^{2+}]$  or in the loading of  $\text{Ca}^{2+}$  stores. Observations that equal amounts of two buffers of similar affinity produced dissimilar effects already suggested that the latter possibilities were not the case. Moreover, experiments were carried out by injecting each buffer already half-saturated with  $\text{Ca}^{2+}$ , so that the free  $[\text{Ca}^{2+}]$  in the injection solutions would have been  $\sim 150$  nM, a little higher than basal free  $[\text{Ca}^{2+}]$  in the oocyte cytosol (Yao *et al.* 1995). As an additional control, we repeated the experiments using solutions of EGTA and BAPTA that contained either no added  $\text{Ca}^{2+}$  or were saturated (1:1 ratio) with  $\text{Ca}^{2+}$ . The results were essentially identical to those in Figs 1 and 2 (data not shown), indicating that the effects of EGTA and BAPTA on  $\text{Ca}^{2+}$  signals did not result from addition or removal of available  $\text{Ca}^{2+}$  ions within the oocyte.

**Figure 2. Buffer actions at varying  $[\text{IP}_3]$**

Representative fluorescence profiles (from different oocytes to those in Fig. 1) show superimposed  $\text{Ca}^{2+}$  transients evoked by increasing photorelease of  $\text{IP}_3$  in the absence of exogenous buffer (upper panels) and after loading increasing concentrations of EGTA (A) or BAPTA (B). Traces correspond to different photolysis flash strengths, indicated in normalized units.

### Positive and negative modulation of IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals by buffers

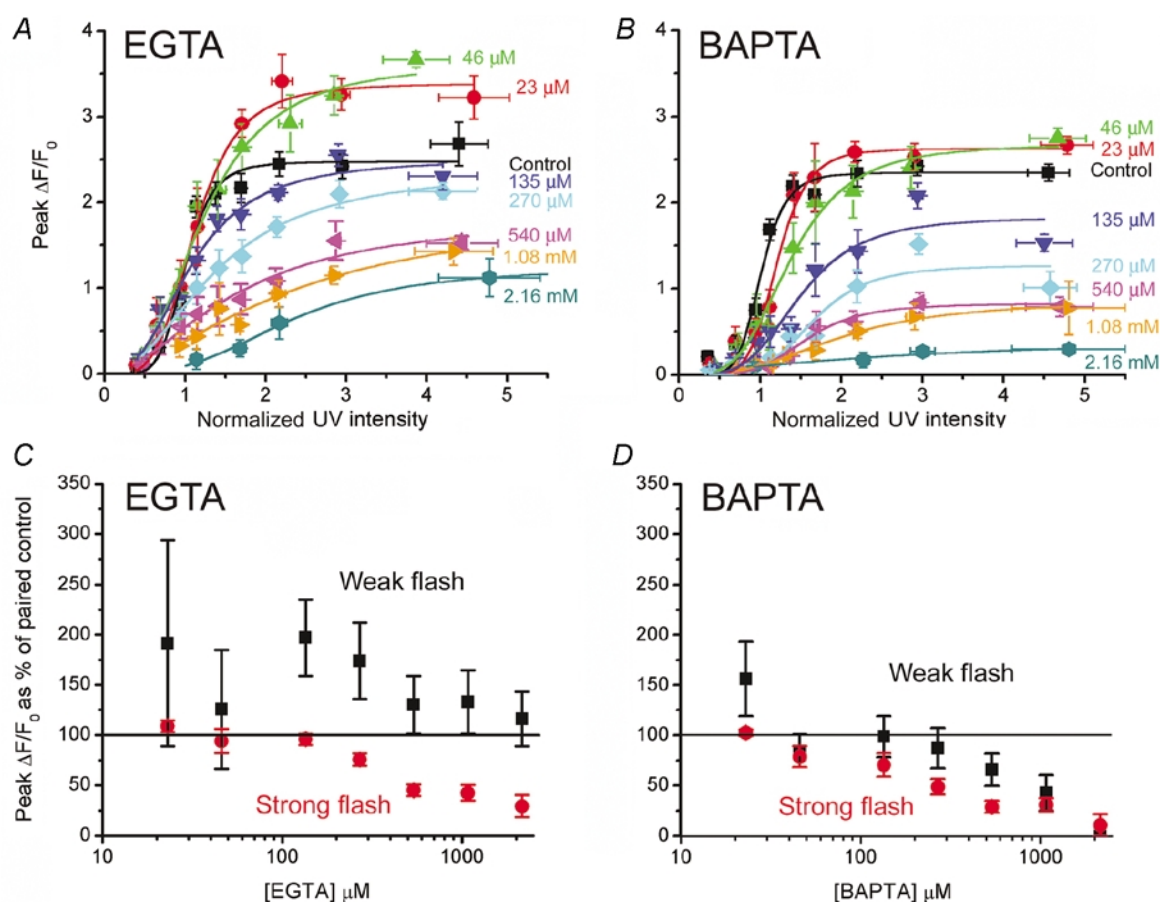

Figure 3A and B shows families of curves plotting the mean peak amplitude of fluorescence signals evoked by increasing photorelease of IP<sub>3</sub> at various concentrations of EGTA and BAPTA, respectively. High cytosolic concentrations (> 135  $\mu$ M) of both buffers appreciably reduced the amplitude of Ca<sup>2+</sup> signals evoked by strong photorelease of IP<sub>3</sub>, with BAPTA being more potent than EGTA. This reduction was expected – in part because the buffers will compete with indicator dye for free Ca<sup>2+</sup> ions. In contrast, Ca<sup>2+</sup> signals evoked by weak photolysis flashes were potentiated by EGTA; as shown in Fig. 3C, plotting Ca<sup>2+</sup> signals evoked by weak (0.6–0.8) and strong (1.9–2.6) flashes at various buffer concentrations relative to control responses without added buffer. Potentiation was strongest at low (< 300  $\mu$ M) concentrations of EGTA, but responses remained greater than control values at concentrations as high as 2 mM EGTA. The slow binding kinetics of EGTA appear to be important for this effect, because little

potentiation was apparent with corresponding concentrations of BAPTA (Fig. 3D).

### Buffers reduce the apparent cooperativity of IP<sub>3</sub>-evoked Ca<sup>2+</sup> liberation

The concentration–response relationships in Figs 3A and B are fitted by Hill curves ( $y = V_{\max}(x^{n_H}/(K^{n_H} + x^{n_H}))$ ; where  $y$  = peak fluorescence ratio ( $\Delta F/F_0$ ) at any given [IP<sub>3</sub>] ( $x$ );  $V_{\max}$  = peak  $\Delta F/F_0$  at saturating [IP<sub>3</sub>]; and  $n_H$  is the Hill coefficient, which gives a measure of the apparent cooperativity of IP<sub>3</sub> action in evoking Ca<sup>2+</sup> liberation. Data from these curves are plotted in Fig. 4, showing the dependence of  $n_H$  (Fig. 4A) and  $V_{\max}$  (Fig. 4B) on concentration of EGTA or BAPTA.

The steep dependence of Ca<sup>2+</sup> liberation on [IP<sub>3</sub>] is likely to arise both from the requirement for binding to more than one subunit of the tetrameric receptor for channel opening and because of positive cooperativity resulting from CICR (Meyer *et al.* 1990; Hirota *et al.* 1995; Marchant & Taylor, 1997; Callamaras *et al.* 1998a). In agreement with this dual

**Figure 3. Buffers both facilitate and depress IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals**

A and B, mean peak amplitude ( $\Delta F/F_0$ ) of Ca<sup>2+</sup> signals as a function of photolysis flash strength, plotted for various intracellular concentrations of EGTA (A:  $n = 21$  oocytes) and BAPTA (B:  $n = 24$ ). Curves were fitted using the Hill equation. C and D, changes in peak fluorescence signal as a function of increasing [buffer] plotted as a percentage of that in the same oocyte before loading buffer. Data are pooled for weak (black symbols) and strong (red) photolysis flashes (respective normalized flash strengths 0.6–0.8 and 1.9–2.6) in the presence of EGTA (C,  $n = 14$ ) and BAPTA (D,  $n = 17$ ).

mechanism,  $n_H$  in control conditions (before adding buffer) was  $\sim 6.3$ , a value greater than expected even if channel opening requires binding to all four subunits. Moreover, progressive increases in buffer concentrations reduced  $n_H$  to a minimal value of about 2 (Fig. 4A). A probable interpretation is that  $\text{Ca}^{2+}$  buffers disrupt the diffusion of  $\text{Ca}^{2+}$  ions between  $\text{IP}_3\text{Rs}$  that normally leads to CICR, and that this communication contributes appreciably to the apparent cooperativity of  $\text{IP}_3$  action. Indeed, the minimal  $n_H$  at high buffer concentrations suggests that binding of  $\text{IP}_3$  to two (or possibly even one) subunits may be sufficient for channel opening. Finally, moderate concentrations of EGTA caused a greater reduction in  $n_H$  than equivalent concentrations of BAPTA (Fig. 4A). Because EGTA impairs  $\text{Ca}^{2+}$  diffusion between

clusters of  $\text{IP}_3\text{Rs}$  rather than between individual  $\text{IP}_3\text{Rs}$  within a cluster (see Discussion), it seems that cluster-cluster interactions predominate in establishing the normally high cooperativity of  $\text{IP}_3$  action.

$V_{\max}$  values derived from Hill fits provide a measure of maximal fluorescence at saturating  $[\text{IP}_3]$ , and are plotted as a function of  $[\text{buffer}]$  in Fig. 4B.  $V_{\max}$  declined progressively with increasing concentrations of BAPTA, whereas a biphasic relationship was apparent with EGTA, with an initial potentiation apparent at 23 and 46  $\mu\text{M}$  EGTA.

### Differential effects of buffers on kinetics of $\text{IP}_3$ -evoked $\text{Ca}^{2+}$ signals

As noted earlier, EGTA and BAPTA exerted very different actions on the kinetics of  $\text{IP}_3$ -evoked  $\text{Ca}^{2+}$  transients; respectively causing an acceleration or prolongation of their decay. This is illustrated in Fig. 5A, showing superimposed responses to strong photolysis flashes in the presence of increasing  $[\text{EGTA}]$  or  $[\text{BAPTA}]$  after normalizing amplitudes to facilitate comparison. Fluorescence decays were fit by mono- or bi-exponential curves (Fig. 5B). In the absence of exogenous buffer, the decay followed a single exponential, with a time constant ( $\tau_{\text{slow}}$ ) of a few seconds that slowed progressively with increasing photorelease of  $\text{IP}_3$ . In the presence of EGTA the decay phase became markedly biphasic (Fig. 5B), with a prominent fast component ( $\tau_{\text{fast}}$ ) and smaller slower component ( $\tau_{\text{slow}}$ ). In the presence of BAPTA a slow decay was prominent, and some oocytes (13/20) also showed a small fast component (Fig. 5B).

Figure 6 shows measurements of time constants of the fast and slow decay components, and their relative weights in contributing toward the overall decline in  $[\text{Ca}^{2+}]$ , plotted as a function of flash strength for various concentrations of EGTA or BAPTA. Several features are evident. (1) In the absence of added buffer,  $\text{Ca}^{2+}$  transients showed a mono-exponential decay with a time constant slowing from  $\sim 1$  s with just-suprathreshold photorelease of  $\text{IP}_3$  to nearly 10 s with stronger photo-release (black symbols, Fig. 6A–D). (2) EGTA caused the decay to become markedly biphasic, with an initial fast decline ( $\tau_{\text{fast}}$ ) that contributed  $> 80\%$  of the total decay (Fig. 6E) and shortened with increasing  $[\text{EGTA}]$  (Fig. 6A). The value of  $\tau_{\text{fast}}$  slowed with increasing  $[\text{IP}_3]$  at low ( $< 50 \mu\text{M}$ ) concentrations of EGTA, but was relatively independent of  $[\text{IP}_3]$  at high ( $> 135 \mu\text{M}$ ) concentrations of EGTA (Fig. 6A). Following the large, fast decay, the remaining small component declined with a time constant ( $\tau_{\text{slow}}$ ) that lengthened slightly with increasing photorelease of  $\text{IP}_3$ , and was slower than in the absence of added buffer (Fig. 6C). (3) Addition of BAPTA greatly slowed ( $\tau_{\text{slow}}$  10–30 s) the major part of the  $\text{Ca}^{2+}$  signal (Fig. 6D). In those oocytes that displayed biphasic kinetics, the initial fast component was much smaller than with EGTA (Fig. 6E), and its time constant ( $\tau_{\text{fast}}$ ) was faster than in controls, but slower than with EGTA (Fig. 6B).

**Figure 4.  $\text{Ca}^{2+}$  buffers reduce the apparent cooperativity of  $\text{IP}_3$  action**

A, Hill coefficients, derived from the curves fitted to data in Fig. 3A and B, are plotted as functions of  $[\text{EGTA}]$  (open circles) and  $[\text{BAPTA}]$  (filled squares). B, plot shows  $V_{\max}$  (maximal fluorescence signal at infinite  $[\text{IP}_3]$ ) derived from Hill-fits as functions of  $[\text{EGTA}]$  (open circles) and  $[\text{BAPTA}]$  (filled squares). Horizontal lines on each graph represent control values (i.e. no exogenous buffer).

## Decay of Ca<sup>2+</sup> transients is dominated by release kinetics, not sequestration

IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals reflect a balance between Ca<sup>2+</sup> liberation through IP<sub>3</sub>Rs into the cytosol and its subsequent removal by processes including buffering, extrusion, re-sequestration via sarco(endo)plasmic reticulum Ca<sup>2+</sup>-ATPase (SERCA) pumps and diffusion into the enormous interior volume of the oocyte (Parker *et al.* 1996). The differing effects of EGTA and BAPTA on the kinetics of Ca<sup>2+</sup> signals (Fig. 6) might thus arise either through modulation of Ca<sup>2+</sup> liberation or through actions on subsequent cytosolic Ca<sup>2+</sup> clearance. To discriminate between these possibilities, we examined the effects of buffers on signals arising from Ca<sup>2+</sup> flux into the cytosol through voltage-gated N-type Ca<sup>2+</sup> channels expressed in the plasma membrane. Opening of these channels by a depolarizing pulse is expected to induce a fixed 'pulse' of Ca<sup>2+</sup> influx – without complications of CICR as with IP<sub>3</sub>Rs – and the decay of the resulting Ca<sup>2+</sup> transient should thus provide a good measure of cytosolic Ca<sup>2+</sup> clearance. Moreover, the spatial distribution of Ca<sup>2+</sup> influx across the plasma membrane is expected to closely mimic Ca<sup>2+</sup> liberation from IP<sub>3</sub>-sensitive sites, as these are distributed as a thin shell close under the membrane (Callamaras & Parker, 1999). Ca<sup>2+</sup> arising from both sources will thus approximate a 2-dimensional sheet, with subsequent diffusion along a radial axis into the interior of the oocyte.

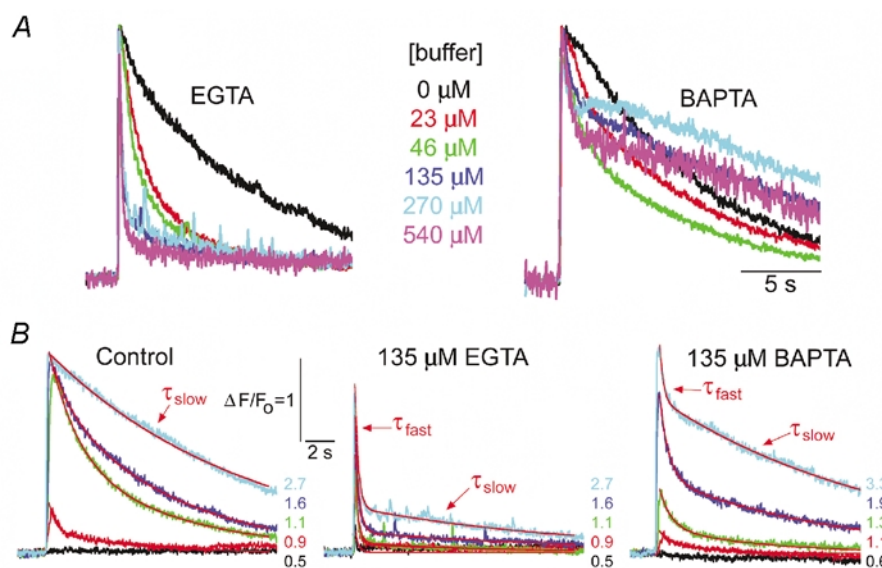

Oocytes expressing N-type channels were voltage clamped at –60 mV and stepped to +30 mV for 300 ms to induce

Ca<sup>2+</sup> influx with a duration matching the rise time of IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals (Fig. 7). After the fluorescence signal had returned to baseline (10 s), a UV flash was applied to photorelease IP<sub>3</sub> (red arrow). Before loading Ca<sup>2+</sup> buffers, signals induced by activation of N-type Ca<sup>2+</sup> channels decayed much more rapidly than those evoked by IP<sub>3</sub>, even though they were of similar amplitude (Fig. 7A). This marked disparity indicates that the slow decay of the IP<sub>3</sub>-evoked signals did not arise through dye saturation – a conclusion further supported by findings of similar decay rates with the low affinity ( $K_d \sim 4 \mu\text{M}$ ) indicator Fluo-4 dextran (not shown).

Thus, the decay of IP<sub>3</sub>-evoked signals does not simply reflect Ca<sup>2+</sup> clearance, but instead is determined primarily by a persistent liberation of Ca<sup>2+</sup> through IP<sub>3</sub>Rs lasting for several seconds. Furthermore, the effects of EGTA and BAPTA are most readily explained by their actions on this prolonged Ca<sup>2+</sup> liberation, rather than on Ca<sup>2+</sup> clearance from the cytosol. Both EGTA (Fig. 7B) and BAPTA (Fig. 7C) produced only a modest speeding of decay of signals resulting from Ca<sup>2+</sup> influx through N-type channels, in marked contrast to their respective actions to accelerate or slow IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals.

## Biphasic Ca<sup>2+</sup> liberation through IP<sub>3</sub>Rs

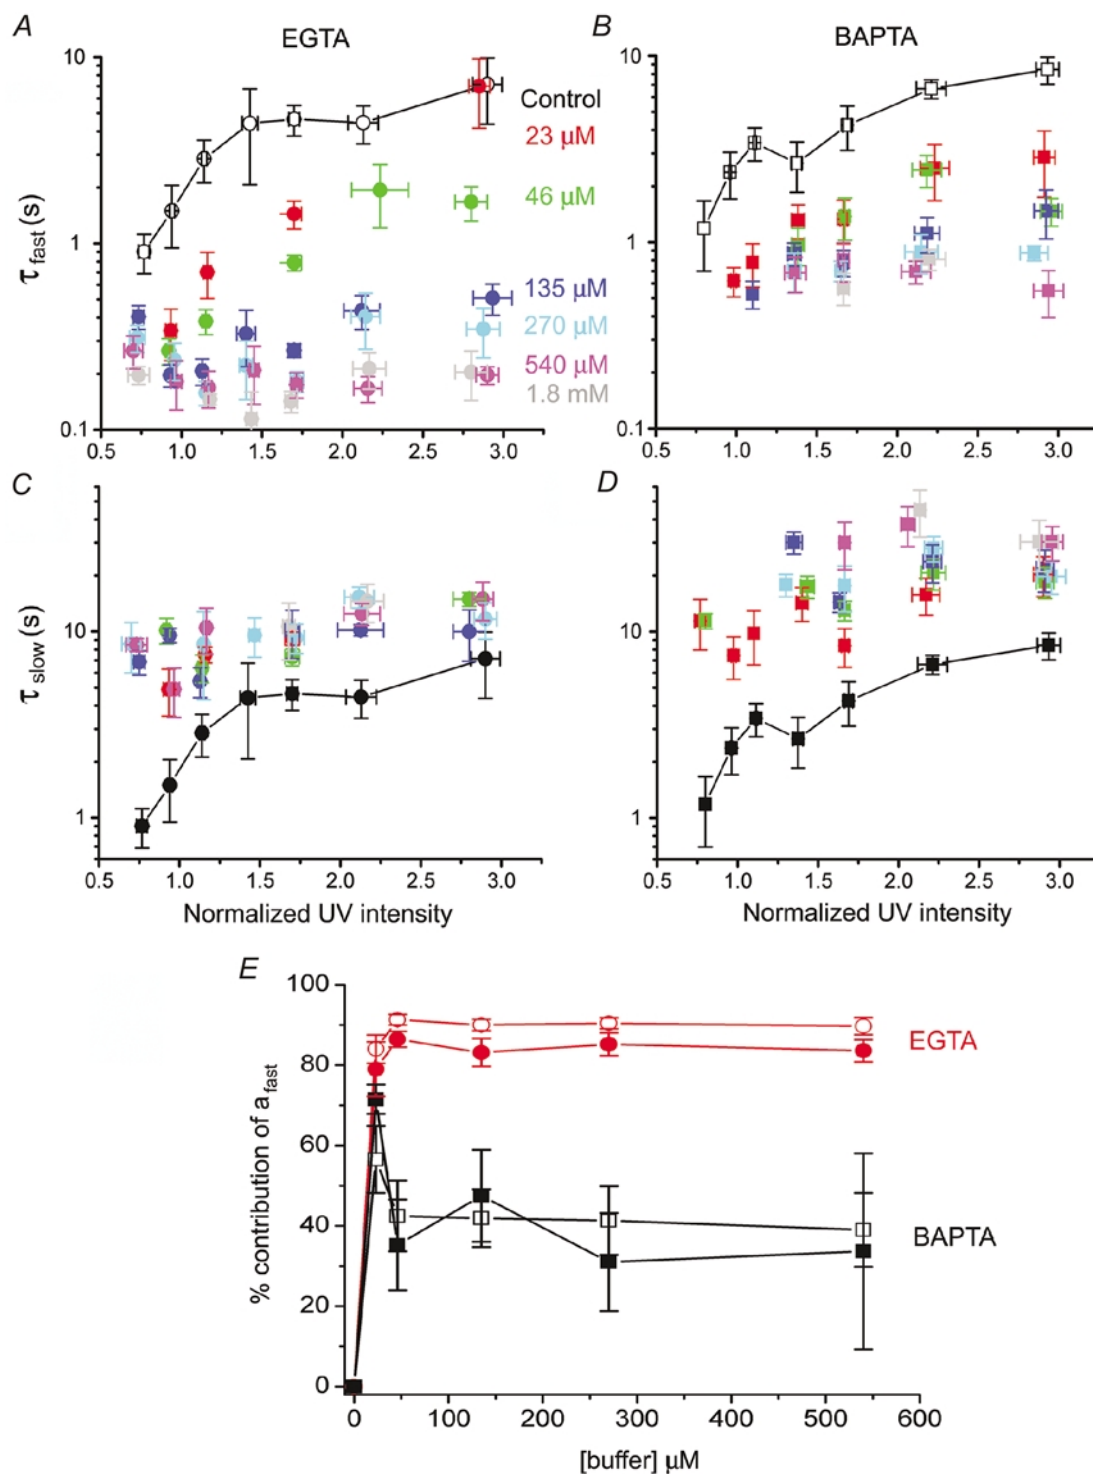

Data from experiments similar to those in Fig. 7 were then used to derive the kinetics of Ca<sup>2+</sup> flux into the cytosol through IP<sub>3</sub>R, assuming that subsequent Ca<sup>2+</sup> clearance follows a first order process with a rate constant ( $k$ ) corresponding to the decay of Ca<sup>2+</sup> signals following influx

**Figure 5. Ca<sup>2+</sup> transients are speeded by EGTA but prolonged by BAPTA**

A, families of curves illustrate Ca<sup>2+</sup> transients evoked by a fixed photolysis flash (normalized strength 2.5) in the presence of the indicated concentrations of EGTA (left) and BAPTA (right). Responses are scaled to same peak height to facilitate comparison. B, Ca<sup>2+</sup> transients evoked by various photolysis flashes of various strengths (normalized strengths indicated) before loading buffer (left); in the same oocyte after loading 135 μM EGTA (middle); and in a different oocyte loaded with 135 μM BAPTA (right). Red curves illustrate fitting of single or double exponentials to derive fast ( $\tau_{\text{fast}}$ ) and slow ( $\tau_{\text{slow}}$ ) decay time constants.

**Figure 6. EGTA and BAPTA differentially affect the fast and slow decay components of IP<sub>3</sub>-evoked Ca<sup>2+</sup> transients**

A and C, graphs show, respectively, the time constants for the fast ( $\tau_{\text{fast}}$ ) and slow ( $\tau_{\text{slow}}$ ) decay components as a function of photolysis flash strength, in the presence of various concentrations of EGTA. B and D, similar data, with corresponding concentrations of BAPTA. Because the decay of Ca<sup>2+</sup> transients without added buffer was mono-exponential, control time constants are repeated in the upper and lower panels (black symbols joined by lines). E, plot shows the relative magnitude of the fast decay component ( $\tau_{\text{fast}}$ : measured as shown in Fig. 5B) at various concentrations of EGTA (red symbols) and BAPTA (black symbols). The amplitudes of the fast and slow components ( $a_{\text{fast}}$  and  $a_{\text{slow}}$ , respectively) were derived at the time of the peak signal from bi-exponential fits, and the graph shows the percentage contribution of  $a_{\text{fast}}$  to the total signal (i.e.  $a_{\text{fast}}/(a_{\text{fast}} + a_{\text{slow}}) \times 100$ ). Open and filled symbols represent signals evoked, respectively, by weak and strong photolysis flashes.

through N-type channels (Fig. 8). Ca<sup>2+</sup> flux from intracellular stores is thus proportional to  $d[Ca^{2+}]/dt + k[Ca^{2+}]$ , where  $[Ca^{2+}]$  is the free cytosolic Ca<sup>2+</sup> concentration as signalled by changes in fluorescence (Parker *et al.* 1996). Consistent with previous observations (Parker *et al.* 1996), control oocytes showed an initial fast spike of IP<sub>3</sub>-evoked Ca<sup>2+</sup> liberation, followed by a lingering 'tail' of Ca<sup>2+</sup> efflux persisting for several seconds (upper traces, Fig. 8B and D). Although the tail component is small (Fig. 8A and C), over time it contributes one-half or more of the total Ca<sup>2+</sup> liberated, and is responsible for the prolonged Ca<sup>2+</sup> transients evoked by IP<sub>3</sub> under normal conditions. EGTA almost abolished the tail component of Ca<sup>2+</sup> liberation (Fig. 8B), thus accelerating the decay of the fluorescent Ca<sup>2+</sup> profile (Fig. 8A). Different to this, the tail component was not significantly altered by BAPTA (Fig. 8D), suggesting that prolonged release of Ca<sup>2+</sup> through the IP<sub>3</sub>R may involve cluster–cluster interactions that are selectively disrupted by slow buffers.

### Changes in spatial distribution of Ca<sup>2+</sup> signals

In addition to their actions on the amplitude and kinetics of IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals, EGTA and BAPTA produced characteristic, and very different, changes in the spatial distribution of Ca<sup>2+</sup> signals (Fig. 9). Control oocytes (without added buffer) often display transient localized Ca<sup>2+</sup> signals (puffs) in response to photolysis flashes within a narrow 'window' of flash strengths (Yao *et al.* 1995), but these were not evident in the oocytes illustrated, and only

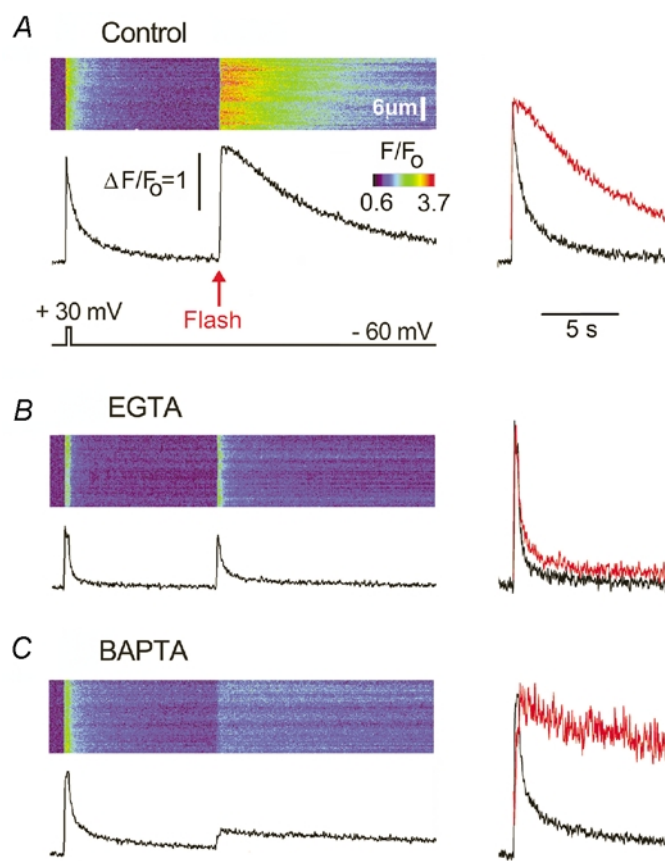

spatially diffuse Ca<sup>2+</sup> waves were observed (Fig. 9A). However, following injection of EGTA (135 μM), the same oocytes showed discretely localized puffs (Fig. 9B: representative of 14/15 oocytes). With weak stimuli puffs arose at discrete sites following differing latencies. Stronger photorelease of IP<sub>3</sub> caused sites to respond almost simultaneously, giving rise to the abrupt, rapidly decaying Ca<sup>2+</sup> transient described earlier. Puffs continued after this initial transient and became more frequent, but smaller, with progressively stronger stimuli. In marked contrast, the same concentration (135 μM) of BAPTA abolished Ca<sup>2+</sup> responses to weak photolysis flashes (10/18 oocytes with normalized flash strengths ≤1.1), and at higher flash strengths oocytes showed only spatially uniform and slowly decaying Ca<sup>2+</sup> signals. We never (0/24 oocytes) observed localized Ca<sup>2+</sup> puffs.

## DISCUSSION

We show that two mobile Ca<sup>2+</sup> buffers with similar affinities but very different binding kinetics affect the spatiotemporal characteristics of IP<sub>3</sub>-evoked Ca<sup>2+</sup> liberation in contrasting ways. EGTA – a buffer with a slow binding rate – causes Ca<sup>2+</sup> signals to become more transient and 'balkanizes' Ca<sup>2+</sup> liberation such that individual release sites act autonomously to generate discrete puffs rather than functioning in concert to generate Ca<sup>2+</sup> waves. On the other hand, BAPTA – a fast buffer – prolongs Ca<sup>2+</sup> transients and promotes a 'globalization' of Ca<sup>2+</sup> signalling as a spatially

**Figure 7. The decay of IP<sub>3</sub>-evoked Ca<sup>2+</sup> transients is largely determined by the kinetics of Ca<sup>2+</sup> release, not sequestration**

A, line-scan image shows a Ca<sup>2+</sup> transient evoked by a 300 ms duration depolarization to +30 mV to activate expressed N-type channels, followed 10 s later by a UV flash to photorelease IP<sub>3</sub>. The lower trace shows the fluorescence profile averaged across a 6.6 μm region of the scan line, and superimposed traces on the right compare the voltage-gated signal (black) with the IP<sub>3</sub>-evoked signal (red) after normalizing to the same peak height. B, corresponding image and traces recorded under identical conditions in the same oocyte after loading 270 μM EGTA. C, similar records in a different oocyte loaded with 270 μM BAPTA. Control records in this oocyte before loading BAPTA were similar to one in A.

uniform elevation without evidence of local release events. These strikingly different actions cannot be explained merely by chelation of  $\text{Ca}^{2+}$  subsequent to its liberation into the cytosol, because  $\text{Ca}^{2+}$  signals generated by influx through voltage-gated channels were affected to a much lesser degree by EGTA and BAPTA (Fig. 7). Moreover, they do not arise through changes in resting free  $[\text{Ca}^{2+}]$  or alterations in  $\text{Ca}^{2+}$  store filling, as similar results were obtained whether buffers were injected either without  $\text{Ca}^{2+}$  or saturated with  $\text{Ca}^{2+}$ . Instead, EGTA and BAPTA appear to act over different time and distance scales to modulate the processes of  $\text{Ca}^{2+}$  diffusion and CICR that shape the regenerative nature of  $\text{IP}_3$ -evoked  $\text{Ca}^{2+}$  liberation.

### Spatiotemporal scales of $\text{Ca}^{2+}$ signalling

$\text{IP}_3$ Rs are organized in *Xenopus* oocytes as tight (*ca* 50 nm diameter) clusters containing several tens of channels, with a mean cluster-cluster spacing of  $\sim 3 \mu\text{m}$  (Callamaras *et al.* 1998a,b; Swillens *et al.* 1999; Shuai & Jung, 2002, 2003). CICR can thus act over two very different spatiotemporal scales – via fast diffusion over nanometre distances between  $\text{IP}_3$ Rs within a cluster to give local  $\text{Ca}^{2+}$  puffs, and much more slowly across micrometre distances between clusters to generate propagating saltatory waves (Fig. 10A: Yao *et al.* 1995; Bootman *et al.* 1997; Berridge, 1997; Callamaras *et al.* 1998a,b; Marchant & Parker, 2000). Depending on their kinetics, buffers may selectively act on one or other of these processes.

Key factors determining the interactions of buffers with  $\text{Ca}^{2+}$  ions are summarized in Table 1, and include: (1) the mean time ( $\tau_{\text{capture}}$ ) and distance ( $d_{\text{capture}}$ ) that a  $\text{Ca}^{2+}$  ion will diffuse before it becomes bound to a buffer molecule; (2) the mean time (dwell time;  $\tau_{\text{dwell}}$ ) a  $\text{Ca}^{2+}$  ion will remain bound to a buffer before dissociating, and the corresponding mean distance ('shuttle' distance;  $d_{\text{shuttle}}$ ) by which the  $\text{Ca}^{2+}$ -buffer complex will diffuse before dissociation. Further, diffusion of  $\text{Ca}^{2+}$  ions in the cytosol is slowed by binding to endogenous, immobile buffers. Less than 10 % of the total  $\text{Ca}^{2+}$  ions in the cytosol are free at any given time, and the apparent diffusion coefficient for  $\text{Ca}^{2+}$  in the oocyte is thereby slowed about 10-fold as compared to free aqueous diffusion (respectively, 20 *vs.* 200  $\mu\text{m}^2 \text{s}^{-1}$ ; Allbritton *et al.* 1992; Yao *et al.* 1995). Buffers, such as EGTA and BAPTA can thus act as a 'shuttle' to facilitate diffusion (Stern, 1992; Roberts, 1994) because, when bound to a mobile buffer molecule, a  $\text{Ca}^{2+}$  ion is 'protected' from binding to immobile sites and is thus carried appreciable distances at a rate only a little slower than that for free aqueous diffusion.

### Buffer actions on inter- and intra-cluster signalling

We present here a qualitative model to account for the actions of EGTA and BAPTA on  $\text{IP}_3$ -evoked  $\text{Ca}^{2+}$  signalling, which is summarized in Fig. 10. This is necessarily simplified, and will require mathematical modelling for rigorous verification, but nevertheless offers useful insights.

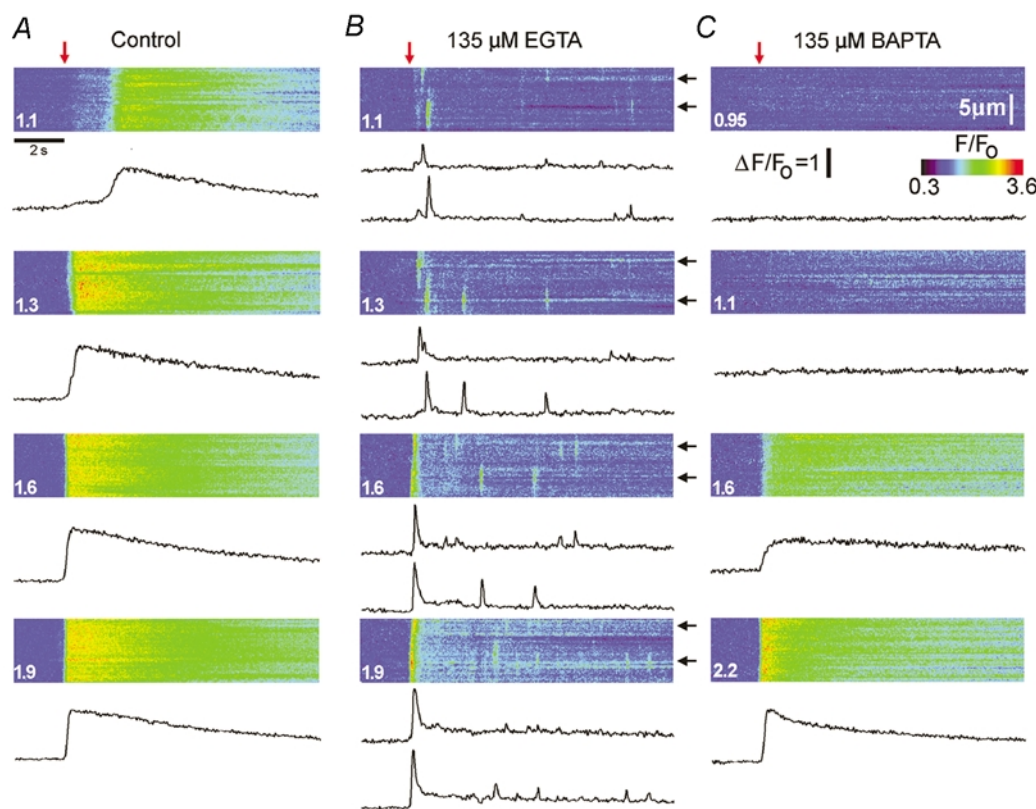

**Figure 8.** EGTA abolishes the 'tail' of  $\text{IP}_3$ -evoked  $\text{Ca}^{2+}$  liberation that normally prolongs  $\text{Ca}^{2+}$  transients

A, fluorescence signals evoked by  $\text{Ca}^{2+}$  entry through voltage-gated channels (bar) and by photoreleased  $\text{IP}_3$  (arrow), before (upper) and after (lower) loading 270  $\mu\text{M}$  EGTA, derived from images similar to Fig. 7A and B. B, rates of  $\text{Ca}^{2+}$  flux into the cytosol derived from the records in A, as described in the text. Traces were smoothed using 15 point adjacent averaging. Calibration bar corresponds to a rate of increase in fluorescence ( $d(\Delta F/F_0)/dt$ ) of 3  $\text{s}^{-1}$ . Inset graphs show the same records with expanded vertical axes to better illustrate the abolition of the persistent 'tail' of  $\text{Ca}^{2+}$  liberation by EGTA. C and D, similar data from a different oocyte, illustrating the lack of action of BAPTA (270  $\mu\text{M}$ ) on the tail of  $\text{Ca}^{2+}$  liberation.

Dealing first with EGTA, we consider how cytosolic diffusion of Ca<sup>2+</sup> would be altered in the presence of 270  $\mu\text{M}$  of this buffer. Its slow on-rate implies that a Ca<sup>2+</sup> ion will diffuse an average distance of about 1  $\mu\text{m}$  before binding to an EGTA molecule (Table 1). EGTA is thus expected to have little effect on short-range Ca<sup>2+</sup> feedback over nanometre distances between individual IP<sub>3</sub>R within a cluster, but it will efficiently capture Ca<sup>2+</sup> ions diffusing over micrometre distances between neighbouring clusters (Roberts, 1994; Horne & Meyer, 1997; Song *et al.* 1998; Callamaras *et al.* 1998a,b; Kidd *et al.* 1999). Once bound, Ca<sup>2+</sup> ions will be unavailable to trigger CICR for prolonged periods ( $\tau_{\text{dwell}} = 0.7\text{--}2$  s: Falcke, 2003), and Ca<sup>2+</sup> bound to EGTA will be shuttled long distances ( $d_{\text{shuttle}} = 28\text{--}50$   $\mu\text{m}$ ) before being 'dumped' in the interior of the oocyte where release sites are absent (Callamaras & Parker, 1999). The overall effect will thus be to more sharply restrict Ca<sup>2+</sup> signals around individual clusters, and reduce free [Ca<sup>2+</sup>] between clusters so as to functionally uncouple them (Fig. 10B). In agreement, EGTA has little effect on puffs (Callamaras & Parker, 2000), yet strongly inhibits Ca<sup>2+</sup>

waves and dissociates global IP<sub>3</sub>-evoked Ca<sup>2+</sup> signals into discrete, localized Ca<sup>2+</sup> release events (Fig. 9: Horne & Meyer, 1997; Kidd *et al.* 1999; Callamaras & Parker, 2000).

In contrast, BAPTA has an on-rate about 100 times faster than EGTA, and binds Ca<sup>2+</sup> ions within a distance (tens of nanometres; Table 1) comparable to the dimensions of an IP<sub>3</sub>R cluster, thereby reducing CICR between individual receptors within the cluster. Subsequently, Ca<sup>2+</sup> bound to BAPTA will rapidly (*ca* 10 ms) be 'shuttled' a few micrometres before dissociating. This is comparable to the inter-cluster spacing, so whereas BAPTA will inhibit *intra*-cluster feedback by Ca<sup>2+</sup> it may actually facilitate *inter*-cluster communication. Moreover, discrete puffs arise only when the Ca<sup>2+</sup> release time at a site (*ca* 50 ms: Sun *et al.* 1998) is short in relation to the inter-cluster diffusion time (Dawson *et al.* 1999; Shuai & Jung, 2003). This condition is fulfilled in the absence of exogenous buffer, but the ability of BAPTA to rapidly shuttle Ca<sup>2+</sup> and thereby speed its diffusion effectively 'smears' the distribution of Ca<sup>2+</sup>, so that the endoplasmic reticulum

**Figure 9. EGTA balkanizes Ca<sup>2+</sup> signals into discrete, autonomous units, whereas BAPTA promotes spatially uniform global signals**

A, line-scan images and fluorescence profiles (averaged over 4  $\mu\text{m}$  regions) showing responses to photolysis flashes (red arrows) of increasing strength (indicated in normalized units) before injecting buffer. B, corresponding records in the same oocyte after loading 135  $\mu\text{M}$  EGTA. Two representative fluorescence profiles are illustrated from each image, recorded at different puff sites (arrowed). C, corresponding records in a different oocyte loaded with 135  $\mu\text{M}$  BAPTA. Records in this oocyte before loading BAPTA were similar to those in A.

(e.r.) approximates a deterministic, spatially continuous  $\text{Ca}^{2+}$  source, rather than an array of loosely coupled, discrete stochastic sources (Dawson *et al.* 1999; Shuai & Jung, 2003).

### Cooperativity of $\text{IP}_3$ -evoked $\text{Ca}^{2+}$ release

In the absence of added buffer,  $\text{Ca}^{2+}$  liberation in the oocyte increases steeply ( $n_H > 6$ ) with  $[\text{IP}_3]$ . This is likely to reflect both the requirement for binding of multiple  $\text{IP}_3$  molecules to open the homo-tetrameric  $\text{IP}_3\text{R}$ , and positive cooperativity introduced by CICR. Our results suggest that the latter is the more prominent factor. High (millimolar) concentrations of both EGTA and BAPTA reduced  $n_H$  to  $\sim 2$ , suggesting that binding of two (or possibly one) molecules of  $\text{IP}_3$  is sufficient for channel opening. Interestingly, moderate concentrations of EGTA (approximately  $25 \mu\text{M}$ ) caused a much greater reduction in  $n_H$  than the same concentrations of BAPTA, further implying that inter-, rather than intra-cluster interactions are the main factor contributing to the high cooperativity under physiological conditions.

### Potentiation of $\text{Ca}^{2+}$ signalling by low $[\text{EGTA}]$

$\text{Ca}^{2+}$  signals evoked by strong photorelease of  $\text{IP}_3$  became progressively smaller with increasing concentrations of EGTA and BAPTA, as might be expected because the buffers will compete with the indicator dye for available  $\text{Ca}^{2+}$  as well as reducing  $\text{Ca}^{2+}$  liberation by impairing CICR. On the other hand, EGTA (but not BAPTA) actually potentiated responses evoked by weak photorelease of  $\text{IP}_3$

by as much as 100 % (Fig. 3C). This surprising finding is consistent with a recent demonstration that slow, mobile  $\text{Ca}^{2+}$  buffers (parvalbumin and EGTA) promote puff activity in *Xenopus* oocytes, probably by sensitizing  $\text{IP}_3\text{R}$  to resting levels of  $\text{IP}_3$  (John *et al.* 2001). Potentiation of  $\text{Ca}^{2+}$  excitability by expression of specific endogenous buffers may, therefore, play an important role in regulating cellular signalling. The underlying mechanism is unclear (John *et al.* 2001), but effects on cluster–cluster interactions are implicated because potentiation is most prominent with slow buffers, appears not to result from changes in resting free  $[\text{Ca}^{2+}]$ , and does not correlate with binding of  $\text{Ca}^{2+}$ -free forms of different buffers to  $\text{IP}_3\text{Rs}$  (Richardson & Taylor, 1993; John *et al.* 2001).

### Cluster–cluster interactions prolong $\text{Ca}^{2+}$ liberation

$\text{Ca}^{2+}$  signals during local  $\text{Ca}^{2+}$  puffs persist for only a few hundred milliseconds (Yao *et al.* 1995; Sun *et al.* 1998), whereas  $\text{Ca}^{2+}$  elevations during global waves decay over several seconds (e.g. Fig. 2). We originally thought that this difference might reflect differences in  $\text{Ca}^{2+}$  clearance, and that the kinetics of  $\text{Ca}^{2+}$  liberation were similar during these local and global events. Specifically, it seemed that  $\text{Ca}^{2+}$  liberated at a ‘point’ source (as during a puff) would rapidly dissipate by 3-dimensional diffuse into the vast volume of the oocyte, whereas the spatially extensive  $\text{Ca}^{2+}$  release during a wave would be cleared primarily by slower processes such as sequestration back into the e.r. (Yao *et al.* 1995). However, the experiment of Fig. 7 indicates that this is not a full explanation, because  $\text{IP}_3$ -evoked  $\text{Ca}^{2+}$  signals

**Figure 10. Cartoon illustrating the distribution of  $\text{Ca}^{2+}$  ions around  $\text{IP}_3\text{R}$  clusters, and how communication between  $\text{IP}_3\text{Rs}$  may be affected by mobile buffers with differing binding kinetics**

A, without added buffer,  $\text{Ca}^{2+}$  ions liberated through open  $\text{IP}_3$  at a cluster diffuse a few micrometres and, depending on  $[\text{IP}_3]$ , may or may not trigger CICR at adjacent clusters. B, EGTA acts too slowly to disrupt  $\text{Ca}^{2+}$  diffusion and CICR within clusters, but binds  $\text{Ca}^{2+}$  ions as they diffuse between clusters and rapidly ‘shuttles’ them away, so as to disrupt cluster–cluster interactions. C, BAPTA binds  $\text{Ca}^{2+}$  ions sufficiently quickly to disrupt  $\text{Ca}^{2+}$  communication between  $\text{IP}_3\text{Rs}$  within individual clusters, whilst promoting  $\text{Ca}^{2+}$  communication between clusters by acting as a rapid  $\text{Ca}^{2+}$  shuttle.

decayed much more slowly than equivalent signals evoked by extracellular Ca<sup>2+</sup> influx through voltage-gated channels. Instead, we conclude that IP<sub>3</sub>-evoked waves are prolonged largely because Ca<sup>2+</sup> efflux from the e.r. is biphasic. That is to say, a large, but rapidly terminating flux during the rising phase of the wave is followed by a 'tail' of Ca<sup>2+</sup> efflux which, though small, is sufficiently prolonged that it greatly slows the decline of cytosolic [Ca<sup>2+</sup>] (Fig. 8A). The actions of EGTA and BAPTA on global Ca<sup>2+</sup> signals to respectively speed and slow their decay can then be understood in terms of their relative effects on the fast and slow components of Ca<sup>2+</sup> efflux. EGTA almost abolishes the slow component while having little effect on the fast component, whereas BAPTA selectively attenuates the fast component and prolongs the slow component (Fig. 8B and C).

Termination of Ca<sup>2+</sup> flux through IP<sub>3</sub>Rs thus appears to involve two distinct processes. Flux at individual clusters acting in isolation (at low [IP<sub>3</sub>], or after uncoupling with EGTA) ceases abruptly and stochastically within ~100 ms, and shows an 'adaptive' property such that it can be reactivated by further elevation of [IP<sub>3</sub>] (Callamaras & Parker, 2000). On the other hand, clusters recruited during a wave show an initial large Ca<sup>2+</sup> efflux with a time course similar to that of puffs, and then abruptly transition to a state in which they continue to 'leak' Ca<sup>2+</sup> at a low rate for several seconds. The mechanisms underlying this transition remain unknown, but the striking action of EGTA to attenuate the slow release suggests that it involves diffusional spread of Ca<sup>2+</sup> between clusters, such that each continues to maintain others in an activated state. Moreover, the importance of the slow release component in shaping Ca<sup>2+</sup> transients further emphasizes the role of buffers in cell signalling. Although the slow Ca<sup>2+</sup> flux is small, its persistence means that the total amount of Ca<sup>2+</sup> liberated is greater than that during the fast component; and attenuation of the slow component by EGTA shortens the duration of Ca<sup>2+</sup> spikes as much as 10-fold.

### Physiological roles of buffers in cellular Ca<sup>2+</sup> signalling

Our results point to the importance of buffering kinetics in shaping the spatial and temporal patterning of Ca<sup>2+</sup> signals generated by intracellular Ca<sup>2+</sup> liberation through Ca<sup>2+</sup>-sensitive release channels – effects that are more complex than for signals arising from a fixed 'pulse' of Ca<sup>2+</sup>, as with Ca<sup>2+</sup> entry through voltage-gated channels (e.g. Lee *et al.* 2000). For convenience we utilized the synthetic buffers EGTA and BAPTA, which are not normally present within cells. However, preliminary experiments with endogenous mobile Ca<sup>2+</sup>-binding proteins (Dargan *et al.* 2003) point out the physiological relevance of our results. In particular, parvalbumin – a mobile Ca<sup>2+</sup> buffer with slow Ca<sup>2+</sup> binding kinetics (Lee *et al.* 2000b; Schmidt *et al.* 2003) – balkanized Ca<sup>2+</sup> signals and accelerated their decay similar to EGTA;

whereas the fast buffer calretinin (Edmonds *et al.* 2000) produced BAPTA-like effects. Although there are obvious differences between small-molecule and protein buffers (such as differing mobility and possibility of protein–protein interactions), the emergent theme is that the kinetics of a buffer are the key parameters defining its actions in shaping IP<sub>3</sub>-mediated Ca<sup>2+</sup> signals. Moreover, this theme is likely to extend to mammalian systems because the clustered distribution of IP<sub>3</sub>Rs in the *Xenopus* oocyte is mirrored in diverse mammalian cells (Bootman *et al.* 1997; Simpson *et al.* 1997). We finally note that ryanodine receptors (RyRs), the other major class of intracellular Ca<sup>2+</sup> release channel, also communicate via CICR (Berridge, 1997), so that their signalling may similarly be susceptible to shaping by mobile Ca<sup>2+</sup> buffers.

### Acknowledgements

Plasmids containing cDNA clones coding for the N-type  $\text{Ca}^{2+}$  channel  $\alpha_{1B-d}$  and  $\beta_3$  subunits were a kind gift from Diane Lipscombe. We thank Dr Angelo Demuro for *in vitro* transcription, expressing N-type  $\text{Ca}^{2+}$  channels in oocytes, and helping with experiments of Fig. 7; and Dr Brian Edmonds for helpful discussion. Funded by NIH grants GM48071 and GM58329.

# Buffer kinetics shape the spatiotemporal patterns of IP3-evoked Ca<sup>2+</sup> signals
